## Abstract

Asked what to study, which career to pursue, or what product to build, large language models (LLMs) often recommend AI-related options. We ask where this tendency comes from by comparing models before and after fine-tuning and by varying how questions are asked. First, pretrained models already include explicit AI/ML terms in the recommendations of 27% of their responses, and their released instruction-tuned versions do so in 59%. Second, fine-tuning models ourselves shows that this rise is not inevitable: general instruction tuning leaves the rate unchanged, but removing the 7% of instruction examples that concern AI cuts it by 14 percentage points, below the level of the pretrained models it starts from. Data rewarding helpfulness raise it by 9 points, while data ranked by the preferences of diverse simulated users lower it by 9. Finally, with models held fixed, asking for the "best" option or for what to do "right now" raises the rate by 8 and 18 points, whereas telling the model it is an AI advisor adds 4. Overall, the tendency starts in pretraining, and what models learn afterward, together with how a question is phrased, decides how strongly it appears.

## 1 Introduction

When users seek open-ended advice from large language models (LLMs), the recommendations can shape which options they consider and, ultimately, their decisions. This makes systematic tendencies in these recommendations important to understand, even when individual suggestions appear reasonable.

One such tendency is pro-AI prominence: the frequent inclusion of AI-related content in open-ended recommendations. Prior work documented such prominence in open-ended advice, and more favorable estimates for AI cases in matched prediction tasks (Trabelsi et al., 2026), while other studies report self-preference in LLM evaluations, preferences for AI-generated content, and provider bias in code generation (Panickssery et al., 2024; Laurito et al., 2025; Zhang et al., 2025). This prominence is not necessarily unjustified, but its origins remain unclear: when an instruction-tuned model recommends AI, the recommendation alone does not reveal whether this tendency reflects pretrained behavior, subsequent training, the system context, or the wording of the request itself.

**Possible sources.** We examine four explanations, which are not mutually exclusive (Figure 1). **H1 (pretraining prior):** pretrained models may already associate AI with innovation, growth, or future value. **H2 (post-training):** post-training may strengthen or weaken pro-AI prominence, depending on the training data, method and objectives. **H3 (AI identity/context):** mentioning AI in the system context, particularly by identifying the assistant itself as AI, may change what it recommends. **H4 (prompt wording):** temporal and superlative wording, such as "right now" and "best", may shift recommendations toward AI-related content.

**Approach.** We pose 20 open-ended advice questions from four domains, each in ten paraphrases, and measure how often a model's recommendation includes explicit AI/ML terms. To test H1 and H2, we compare ten released Base–Instruct pairs and train eleven pretrained models with six post-training recipes, comparing each recipe with its parent checkpoint. To test H3 and H4, we vary the system message and the wording of the question for ten instruction-tuned models.

**Main findings.** Pro-AI prominence is already substantial in pretrained models, consistent with H1, and far higher in their released instruction-tuned counterparts. Controlled post-training shows that this shift is not a generic effect of instruction tuning (H2): general supervised fine-tuning (SFT) leaves pro-AI prominence almost unchanged,

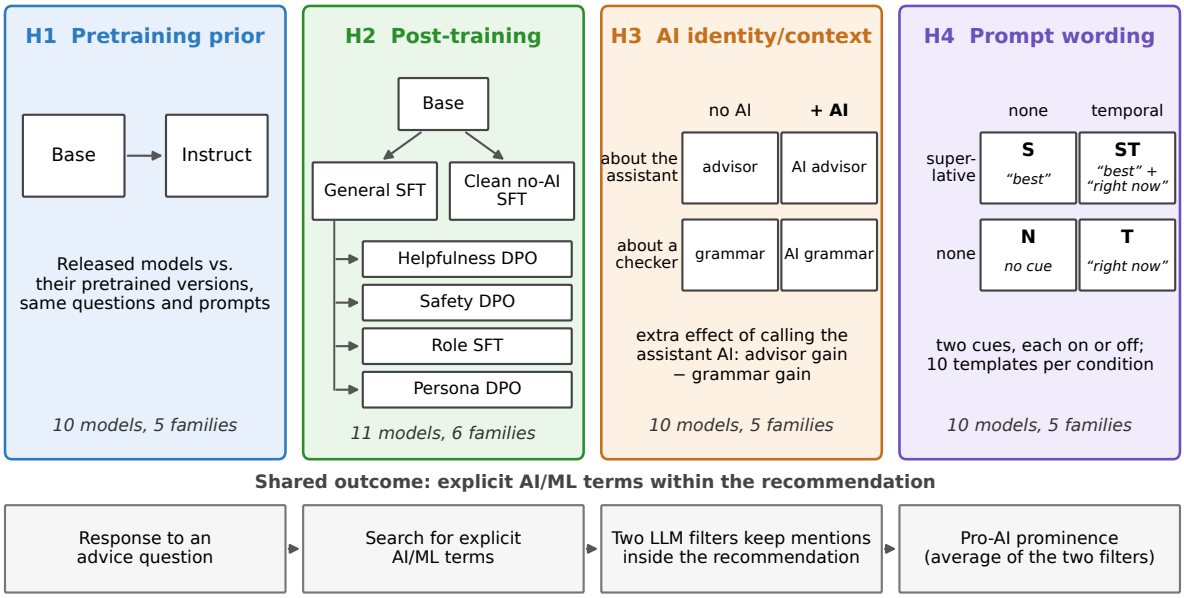

Figure 1: Study design. Top: the four possible sources of pro-AI recommendation prominence and the comparison that tests each; controlled branches are compared with their immediate parent. Bottom: the outcome shared by all comparisons.

whereas other training recipes raise or lower it depending on their data. At inference time, temporal and superlative wording (H4) raise pro-AI prominence far more than AI cues in the system context (H3), and identifying the assistant itself as AI adds no significant further increase.

## 2 Related Work

LLM recommendations often reflect factors beyond the substance of a request. Name cues affect employment and salary recommendations (Nghiem et al., 2024), while demographic and small linguistic cues affect educational recommendations (Shailya et al., 2025; Benedetto et al., 2026). Research has also examined popularity bias in LLM recommenders and changes in product recommendations under different framing (Lichtenberg et al., 2024; Filandrianos et al., 2025).

### 2.1 Bias across training stages

Bias in LLM behavior reflects both pretraining and later training. Instruction-tuned models were shown to exhibit stronger decision biases than Base or less tuned models, yet experiments that vary instruction datasets suggest that several biases follow the pretrained model more closely than the later training data (Itzhak et al., 2024, 2025). These studies compare released models or exchange whole instruction datasets; we instead remove one content category from otherwise identical instruction data and compare preference-optimization recipes applied to the same checkpoint. Controlled studies also show that changes to AI-related text during pretraining affect later alignment behavior, even after SFT and Direct Preference Optimization (DPO), and that small differences near the end of pretraining change responses to the same subsequent preference training (Tice et al., 2026; Lu et al., 2026).

Preference optimization was shown to reinforce biases in training feedback, including through methods such as DPO (Rafailov et al., 2023): biased preference rewards increase models' tendency to agree with users, while preference models favor simple features such as length, technical language, and agreement (Shapira et al., 2026; Bharadwaj et al., 2026). Together, these findings suggest that both training history and post-training choices matter; we test their effects on pro-AI recommendations.

### 2.2 Prompt and system-context effects

Model behavior also varies with prompt wording. Evaluation results based on a single instruction template differ from averages across paraphrases, and even meaning-preserving edits substantially change outcomes (Mizrahi et al., 2024; Sclar et al., 2024). Specific effects include apparent publication dates favoring newer passages during reranking and context cues changing how models respond to assumptions in user requests (Fang et al., 2025;

Cheng et al., 2026). Targeted prompt changes are also often difficult to distinguish from ordinary sensitivity to wording (Yang et al., 2026).

System prompts provide another source of variation. Assigning roles to an assistant was shown to affect its answers without consistently improving task accuracy (Zheng et al., 2024). We therefore distinguish changes caused by wording and surrounding context from those caused by identifying the assistant as AI.

### 2.3 AI as a subject of preference

AI is itself a subject of model preferences. LLM evaluators were shown to favor their own generations, while preferences for LLM-generated communication and for evaluators' own model-generated résumés have been observed in other decisions (Panickssery et al., 2024; Laurito et al., 2025; Xu et al., 2025). Provider preferences also appear in code generation and recommendations among competing AI models (Zhang et al., 2025; Dubash and Friedler, 2026). These effects concern who produced the content or which provider is favored, rather than whether AI or ML appears within the recommendation itself. Closest to our study, prior work documented AI prominence in open-ended recommendations and more favorable estimates for matched AI cases in salary and program-completion tasks (Trabelsi et al., 2026). Whereas that work documents the phenomenon, we study where it comes from, across pretraining, controlled post-training, and inference-time prompts.

## 3 Experimental Design

### 3.1 Recommendation task

We study open-ended advice questions with many plausible answers. The four domains are **Study**, **Career**, **Startup**, and **Scientific Research**. Study, Career, and Startup follow Trabelsi et al. (2026), who chose domains covering consequential choices for which users commonly seek LLM advice. We add Scientific Research because researchers widely use LLMs in their work (Liao et al., 2025), and LLMs are increasingly studied as sources of research ideas (Si et al., 2025). Each domain contains five conceptual questions, each asked in ten fixed paraphrases. The questions are in English and contain no information about the person asking. All comparisons except the wording test ask every question with both a superlative and a temporal cue (e.g., "What is the best {concept} right now?"); the wording test varies these cues. All responses are generated with temperature 0, top-p 1, a 512-token output limit, and seed 12345, with thinking disabled for Qwen models.

### 3.2 Primary outcome

We first detect explicit AI/ML terms (e.g., artificial intelligence, machine learning, deep learning, LLMs and generative AI; full list in Appendix A.5) using fixed lexical patterns, then use two LLM filters to exclude mentions outside the recommendation itself. Responses without such terms are counted as negative. Each filter must answer with a single yes/no label; any other output (0.1% of DeepSeek and under 0.01% of Qwen judgments) is invalid and treated as missing rather than negative.

We use Qwen3.6-27B and DeepSeek-V4-Flash as the two filters. Each filter's rate is computed over the responses it classified validly, and the two rates are averaged with equal weight for each model, condition, and question.

Our measure of pro-AI prominence is the share of responses with explicit AI/ML terms within their recommendations, averaged over the two filters. Responses without a recommendation count as zero, so the measure reflects how often a user who asks the question receives an AI recommendation. Empty responses are excluded rather than counted as zero (Appendix A.5).

Because LLM-based judgments can depend on the evaluator, we also examine the two filters separately (Verga et al., 2024; Thakur et al., 2025). The two filters give nearly identical effect estimates ($r = 0.990$) and agree on which effects are significant, except for one small effect in the AI-context test (Appendix Table 15). On 200 detector-positive responses labeled by a human expert, the measure agrees with the expert on 85.2% (95% CI [81.0, 89.5]), with 96.9% precision and 86.6% recall (Appendix A.12).

### 3.3 Statistical analysis

Effects are calculated from matched experimental conditions, averaging equally across the evaluated models and the 20 questions (five per domain). The 20 questions are our statistical units; the ten paraphrases of a question are treated as repeated wordings of it, not as separate observations.

We compute 95% confidence intervals by resampling questions within each domain (20,000 bootstrap samples).

Significance is tested by flipping the signs of the 20 question-level effects in all $2^{20}$ possible ways (two-sided exact test of the null hypothesis that each question's effect is equally likely to be positive or negative). We apply Holm correction separately within the four prespecified hypothesis families (H1: one test; H2: six; H3: three; H4: three), using $\alpha = 0.05$.

## 4 How Post-Training Changes Pro-AI Prominence

We first ask whether pro-AI prominence is already present before instruction tuning, and whether subsequent training consistently amplifies it. We address these questions through released Base–Instruct comparisons and controlled experiments with specific post-training recipes.

### 4.1 Released Instruct models show a large shift

Released Instruct checkpoints include explicit AI/ML terms within recommendations substantially more often than their pretrained Base counterparts. Across ten matched Base–Instruct model lines from five open-weight model families, pro-AI prominence increases by an average of 32.48 percentage points (95% CI [29.46, 35.39]; Holm-adjusted $p < .001$). On average, 26.80% of responses from released Base checkpoints and 59.28% from released Instruct checkpoints recommend an option with explicit AI/ML terms.

Both checkpoints receive the same three fixed plain-text input formats, designed so that either checkpoint type completes them as an answer; their results are averaged equally. The high rate in Base checkpoints shows that pro-AI prominence does not require instruction tuning. Which training steps raise it is not isolated by this comparison; the controlled experiments below address that question.

### 4.2 Controlled post-training reveals different effects

We next examine whether different post-training recipes consistently change prominence in the same direction. We evaluate eleven model lines from six families in a controlled training tree. General SFT and Clean no-AI SFT start from the pretrained Base checkpoint, while Helpfulness DPO, Safety DPO, Role SFT, and Persona DPO start from General SFT. Each procedure is compared with its immediate parent under the same fixed input formats. The two SFT branches compare ordinary instruction tuning with tuning on the same data minus its AI-related examples; the four branches built on General SFT add common later stages: helpfulness, safety, or persona/value-oriented preference optimization, or role-conditioned instruction tuning.

Figure 2 places these six controlled comparisons alongside the released Base–Instruct contrast. Because the comparisons start from different checkpoints, they are not successive steps of one training run.

**General SFT changes little.** General SFT uses a 60k-example instruction mixture based on Tülu 3, UltraChat, and OpenAssistant-style conversations (Lambert et al., 2025; Ding et al., 2023; Köpf et al., 2023). It changes pro-AI prominence by only $+0.02$ pp on average (95% CI $[-1.58, 1.73]$; Holm-adjusted $p = .996$), with effects of both signs across models (Appendix Figure 4).

**Clean no-AI SFT lowers pro-AI prominence.** A different result emerges when the instruction data are filtered. Clean no-AI SFT uses the same instruction pool after removing the 7.2% of examples that are AI/ML/LLM-related. Relative to Base, it reduces pro-AI prominence by 13.89 pp (95% CI $[-16.09, -11.60]$; Holm-adjusted $p < .001$). Its absolute level falls from 24.64% in Base to 10.74%, so SFT does not always move pro-AI prominence in the same direction.

**Preference-training branches move in opposite directions.** Helpfulness DPO uses a 108k helpfulness-preference mixture including Tülu preference data, UltraFeedback, and HelpSteer2-style pairs (Cui et al., 2024; Wang et al., 2024b). Persona DPO uses 20k response pairs ranked by the persona/value preferences of synthetic users, based on PERSONA (Castricato et al., 2025).

Helpfulness DPO raises pro-AI prominence by 9.48 pp (95% CI [7.37, 11.60]; Holm-adjusted $p < .001$). Persona DPO moves in the opposite direction, lowering it relative to General SFT by 8.95 pp (95% CI $[-10.76, -7.15]$; Holm-adjusted $p < .001$).

The shared General-SFT starting point makes this contrast particularly informative: the two DPO branches differ by approximately 18 percentage points in their estimated effects. Applying preference optimization therefore does not imply a uniform direction of change; the associated training recipe matters. We discuss possible reasons in Sec-

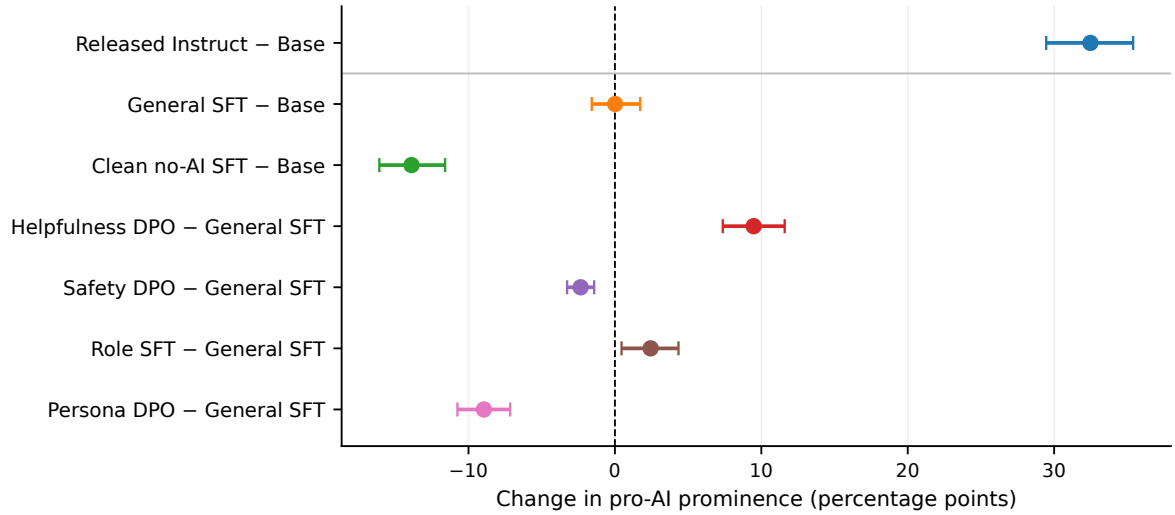

Figure 2: Released Base–Instruct contrast (top) and six controlled post-training comparisons. Markers show effects with 95% confidence intervals. Each controlled branch is compared with its immediate parent, as identified by the row labels.

tion 6.

Safety DPO, trained on 20k safety-preference pairs from PKU-SafeRLHF (Ji et al., 2025), produces a smaller but significant decrease ($-2.34$ pp, 95% CI $[-3.27, -1.42]$; Holm-adjusted $p = .003$). Role SFT, trained on 20k role-conditioned dialogues from ZenMoore/RoleBench (Wang et al., 2024a), shows no significant change ($+2.44$ pp; Holm-adjusted $p = .136$).

Post-training therefore does not uniformly amplify pro-AI prominence: the direction and size of each change depend on the training recipe rather than the training stage.

## 5 Prompt-Level Effects

Recommendations may also change with the input alone, without any change to model weights. We therefore keep model weights fixed and investigate two possible influences at inference time, each on ten instruction-tuned model lines from five families: the criteria expressed in the user's request and explicit AI cues in the system context.

### 5.1 Temporal wording and superlatives both increase explicit AI/ML recommendations

We first vary only the wording of the user's question, using each model's chat template. We vary two cues, each present or absent: a superlative cue (*best*, *strongest*, or *most promising*) and a temporal cue (*right now*, *currently*, or *at present*). This yields four conditions: N (neither), S (superlative only), T (temporal only), and ST (both); for example, an ST prompt is "What is the best {concept} right now?" Each condition has ten paraphrase templates; in five of them (P6–P10), the conditions share a sentence frame and differ only in the cues (Appendix Tables 9 and 10). For each cue, we report its average effect across both settings of the other cue, and we test their interaction. Figure 1 summarizes this design.

Pro-AI prominence rises from 47.05% without either cue to 73.03% with both (Figure 3). The temporal cue raises pro-AI prominence by 17.88 pp (95% CI [14.61, 21.35]; Holm-adjusted $p < .001$), and the superlative cue by 8.10 pp (95% CI [5.49, 10.75]; Holm-adjusted $p < .001$). We find no significant interaction, so the results are compatible with additive effects (+2.25 pp, 95% CI $[-1.00, 5.35]$; Holm-adjusted $p = .246$). Notably, neither cue explicitly requests AI, yet their combination raises pro-AI prominence by approximately 26 percentage points relative to using neither cue.

Asking for what is *current* or *best* thus pushes recommendations toward AI. This extends earlier work on recency and prompt wording effects, which did not test AI recommendations, to open recommendation questions (Fang et al., 2025; Mizrahi et al., 2024; Sclar et al., 2024).

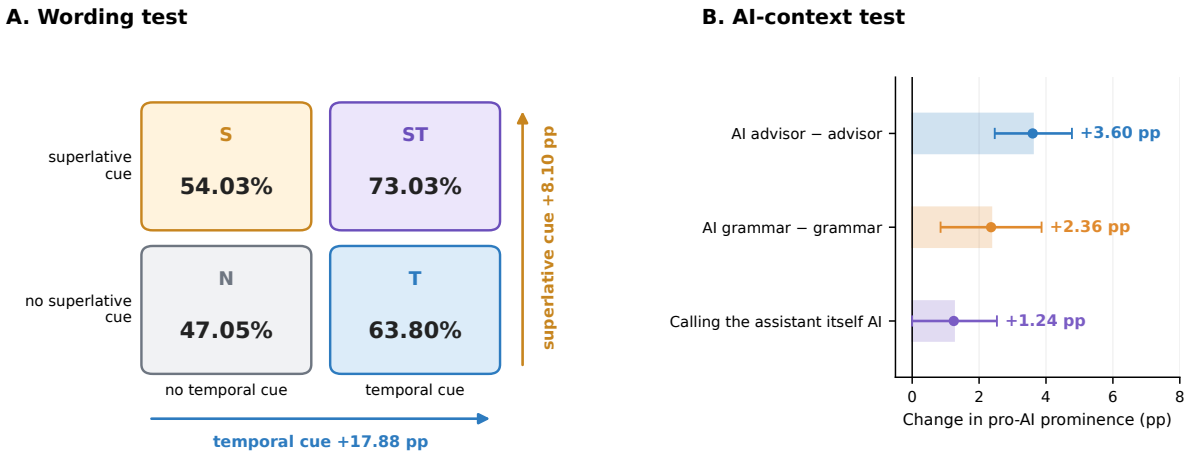

Figure 3: Prompt-level effects on pro-AI prominence. Left: the percentage of responses with explicit AI/ML terms in their recommendations, in each of the four wording conditions (design in Figure 1); arrows show the average increase from each cue. Right: the AI-context effects of adding *AI* to the advisor and grammar-checker messages, and the difference between the two, with 95% confidence intervals.

| Condition | System message |
|---|---|
| Advisor | You are an advisor. |
| AI advisor | You are an **AI** advisor. |
| Grammar | This conversation will be sent to a grammar-checking system as part of routine quality control. |
| AI grammar | This conversation will be sent to an **AI** grammar-checking system as part of routine quality control. |

Table 1: System messages in the AI-context test. Each message ends with "Answer the user's question directly."; within each pair, only the word *AI* differs.

### 5.2 AI context produces small shifts in prominence

So far, we have examined how the wording of a question affects recommendations. We next examine a different possibility: whether explicitly mentioning AI in the system context changes recommendations, and whether calling the assistant itself AI matters more than mentioning AI elsewhere in the system message. We compare two matched pairs of system messages (Table 1), keeping the user questions fixed at the ST wording in all conditions. In the advisor pair, "You are an advisor" becomes "You are an AI advisor." In the grammar-checker pair, the "grammar-checking system" that will receive the conversation becomes an "AI grammar-checking system." Figure 3 (right) shows both effects and their difference.

Adding *AI* to the advisor role increases pro-AI prominence by 3.60 pp (95% CI [2.47, 4.78]; Holm-adjusted $p < .001$). Adding *AI* to the grammar context increases it by 2.36 pp (95% CI [0.85, 3.87]; Holm-adjusted $p = .026$).

**Difference between the two AI-context effects.** The additional effect of AI self-identity is the difference between these two changes: (AI advisor − advisor) − (AI grammar − grammar). A positive value means that calling the model itself an AI matters more than mentioning AI elsewhere in the system message. This difference is +1.24 pp (95% CI [−0.00, 2.53]; Holm-adjusted $p = .132$), so we find no significant additional effect for calling the assistant itself AI, on average across the ten model lines; the increment is positive for five of them (Appendix Figure 4).

### 5.3 Prompt wording matters more than the AI identity label

The prompt changes differ sharply in size. Temporal wording changes pro-AI prominence by roughly 18 pp and superlative wording by roughly 8 pp, compared with roughly 2–4 pp when *AI* is added to either system context. In these tests, ordinary recommendation wording therefore has a larger effect than the AI-identity label. The two manipulations answer different questions: wording changes the user request, whereas the matched system-message test keeps the recommendation question fixed.

## 6 Discussion

Recent work found that models often recommend AI, but did not call this recommendation pattern bias, because no reference says how often AI

should be recommended (Trabelsi et al., 2026). Our comparisons do not need such a reference: each holds the advice question fixed, yet pretrained and instruction-tuned versions, models trained on different data, and models given different system messages recommend AI at very different rates, from 11% after Clean no-AI SFT to 73% when the question asks for the best option right now. Whatever the appropriate rate is, they cannot all be right. We therefore call a shift toward AI-related options in what models recommend, relative to the same question under another condition, *pro-AI bias*.

The largest shifts come from factors that add little information about the user's needs. A user asking for advice already wants the best option for their current situation, yet saying "best" or "right now" pushes models strongly toward AI. Released Instruct checkpoints recommend AI-related options far more often than their Base counterparts; Base models are not explicitly trained to answer questions, but both versions receive identical prompts, designed so that either answers them. Telling the model that it is an AI advisor, or that the conversation will reach an AI grammar checker, also increases AI-related recommendations, although neither changes what would serve the user.

**Training data.** Removing only the 7.2% of instruction examples that concern AI does not merely prevent an increase: it lowers pro-AI prominence below its pretrained baseline, whereas General SFT on the full data leaves it nearly unchanged. One explanation is that ordinary instruction data pull in two directions: most examples encourage a broad range of answers, whereas the AI-related examples reinforce AI as a ready answer, and in General SFT the two roughly cancel. Previous work shows that instruction data selection substantially affects the balance of learned capabilities (Dai et al., 2025), and that AI-related discourse during pretraining influences later model behavior (Tice et al., 2026).

**Preference objectives.** Preference models are known to reward specific features of a response, such as length or technical language, and not only its quality (Bharadwaj et al., 2026), so DPO could favor answers that sound impressive, such as recommending AI. Yet Helpfulness DPO and Persona DPO apply the same method to the same checkpoint and move pro-AI prominence in opposite directions: the preference data, not the method, determine the direction. Helpfulness-oriented feedback may favor solutions perceived as broadly capable, making AI an attractive answer to underspecified requests. Persona DPO instead uses feedback drawn from heterogeneous synthetic personas and opinion-dividing questions (Castricato et al., 2025); learning that the best answer depends on who is asking may make models less inclined to push a single default answer, such as AI.

**Implications.** Directional tendencies matter in open-ended advice, where recommending one plausible option directs attention away from others; this connects our findings to the broader study of biases in recommendation selection (Klimashevskaia et al., 2024). AI-related instruction data, helpfulness preferences, and prompt framing may each make AI more accessible as a broadly desirable answer, especially when a request emphasizes performance or current relevance. Whether models favor AI beyond what the suitability of the alternatives warrants remains open; answering it requires comparing AI and non-AI recommendations under matched user needs and known differences in suitability. Because model evaluation is sensitive to prompt formulation (Mizrahi et al., 2024), such comparisons should span multiple plausible requests.

## 7 Conclusion

Pretrained models already recommend AI often, and their released instruction-tuned versions do so far more. Yet this rise is not inevitable: the data a model is trained on can raise or lower the tendency, and ordinary words such as "best" and "right now" push models toward AI more than telling them that they are AI. Because the same question receives such different answers depending on training and wording, these shifts reflect the models rather than the needs of the user asking. Developers can therefore shape pro-AI prominence through their choice of training data and preference objectives, and evaluations of LLM advice should test several phrasings of the same request.

## Limitations

We measure explicit AI/ML terminology within recommendations, not their quality or whether AI-related advice is justified. This measure can miss implicit AI recommendations, and compared with a human expert it misses some explicit ones (86.6% recall), so its absolute rates are conservative.

Base checkpoints establish that the tendency is already present, but not its origin within pretrain-

ing. Recent enthusiasm for AI may contribute to this tendency, but further research is needed to determine its influence. Controlled comparisons evaluate complete training recipes rather than isolating individual mechanisms, and each branch has only one training run per model. Statistical inference treats the evaluated models as fixed and resamples questions; the findings may differ across other models, languages, domains, and settings.

# A Supplementary Material

This appendix specifies the model panels, interventions, prompts, measurement, and statistical analysis underlying the 13 primary contrasts. The primary outcome is the equal-weight ensemble of two explicit-AI/ML false-positive filters, applied to every detector-positive response. All inferential results below use the four prespecified domains and treat the evaluated models as fixed.

## A.1 Model/checkpoint registry and analysis samples

The controlled analysis contains 11 model lines from six families. A branch is included in a matched comparison only when both required checkpoints are present; no missing branch is filled in. Table 2 gives the public pretrained identifiers. The machine-readable `training/checkpoint_registry_final.tsv` records every controlled branch. Repository names hosted by the authors and exact revisions are redacted in the anonymous-review package because those identifiers can reveal authorship; the public Base model identifiers and revisions remain recorded.

The released panel contains ten Base–Instruct pairs from five family clusters. H1 compares each pair, and H3 uses its ten Instruct checkpoints. Because Llama-3.1-70B did not complete all experimental runs, H1 and H3 use Qwen3-8B in its place; the H4 wording test, where it is available, uses meta-llama/Llama-3.1-70B-Instruct instead of Qwen3-8B (Table 4).

| Analysis | Model lines | Families |
|---|---|---|
| Released Base–Instruct (H1) | 10 | 5 |
| Controlled post-training (H2) | 11 | 6 |
| AI system context (H3) | 10 | 5 |
| Wording factorial (H4) | 10 | 5 |

Table 5: Fixed primary panels.

## A.2 Training data and schedules

For General SFT, the data-building filters require no more than 2,048 tokens and a final assistant turn. Clean no-AI SFT is constructed from the same General SFT source mixture using `Qwen/Qwen3.6-27B` as a fixed binary AI-content filter. Its system instruction marks an item positive when a reasonable reader would understand it as referring to artificial intelligence, machine learning, deep learning, neural networks, LLMs or foundation models, generative AI, chatbots, AI assistants or agents, AI-generated or AI-assisted tools, model training or inference, or a named AI system/model/tool. Generic software, algorithms, automation, statistics, data, robots, and technology remain negative unless the AI meaning is clear. The user instruction requires exactly one token, 1 or 0. Generation uses temperature 0, top-$p = 1$, at most two output tokens, and seed 12345; any chunk marked 1 causes the original item to be removed. The verified dataset contains 55,680 items. Clean no-AI SFT therefore measures the complete filtered-training recipe rather than isolating topic removal at a matched training-set size.

The fixed training configuration specifies one epoch, a maximum sequence length of 2,048 tokens, bfloat16 (BF16), per-device batch size 1, and global batch size 64. The native SFT branches use learning rate $5 \times 10^{-6}$; DPO branches use $5 \times 10^{-7}$ with DPO parameter $\beta = 0.1$. Gradient accumulation is set from GPU count to preserve the global batch. The training-data compiler seed for General SFT, Helpfulness DPO, Safety DPO, Role SFT, and Persona DPO is 13. Table 3 shows the controlled branch structure. The archived registry and training files fix the exact training setup; author-hosted identifiers are redacted here for anonymous review. No optimizer or packing setting is assumed beyond what the archived training files record.

## A.3 Domains, concepts, and full P1–P10 prompt construction

The four domains are Study, Career, Startup, and Scientific Research.

For P1–P4 in the temporal-only and neither conditions, the following concept-specific noun/action mappings keep the prompts grammatical (Table 8)

The P1–P4 wording variants differ in sentence form as well as cue wording; P6–P10 use parallel sentence frames across the four conditions.

## A.4 System context and input formats

The native-chat runs use either no system message or one of the four messages in Table 1. All H3 system conditions use the superlative-plus-temporal ($ST$) P1–P10 user questions (Tables 9 and 10). H4 uses all four $N/S/T/ST$ P1–P10 wording conditions, without an added system message.

The three raw wrappers are:

```
Requester: {question}
Respondent:
Question: {question}
Answer:
Input: {question}
Output:
```

Table 3: Controlled branch coverage. Exact author-hosted repository identifiers and trained-checkpoint revisions are redacted for anonymous review; the accompanying registry preserves the branch structure with anonymized repository fields.

For checkpoint comparisons, the no-system effect is computed separately in each wrapper and the three wrapper-level contributions are then equally averaged. Native chat is used for H3/H4 and is never averaged with raw delivery. Final generation uses temperature 0, top-$p = 1$, at most 512 output tokens, seed 12345, and no stop string.

### A.5 Explicit AI/ML measurement and filtering

The binary outcome records whether an explicit AI/ML term occurs *within an actual recommendation*. First, the fixed `project2_explicit_ai_ml_v1` detector applies NFKC Unicode normalization, removes the two fixed AI-bearing system-message strings reproduced above when they occur as response echoes, and searches for the prespecified terminology. The positive terms include artificial intelligence, machine learning, deep learning, neural networks, statistical learning, reinforcement learning, language models/LLMs, foundation models, generative AI, NLP, computer vision, speech recognition/synthesis, recommendation systems, RAG, prompt engineering, AI agents and assistants, chatbots, transformer and diffusion models, MLOps, AIOps, ChatGPT, OpenAI, GPT, and standalone AI/ML. Terms such as data science, generic automation, robotics, and general software or computing do not, on their own, trigger the detector. The full fixed regular expressions are implemented in `evaluation/scripts/project2_explicit_ai_ml.py`.

A non-empty detector-negative response is assigned zero. Every detector-positive response is passed independently to Qwen3.6-27B and DeepSeek-V4-Flash to determine whether the explicit mention is part of a recommended option, method, tool, product, system, or approach. Incidental references, system-prompt echoes, assistant self-descriptions, and mentions outside a substantive recommendation do not count. The filter task is intentionally framed as a *false-positive* decision: `N` means at least one AI/ML mention belongs to a substantive recommendation (final score 1), whereas `Y` means no such mention does (final score 0). A valid filter returns exactly `Y` or `N`; invalid outputs remain missing, not zero.

Each filter receives the domain, concept, user question, and complete generated response. The

| Alias | Family | Base checkpoint | Instruct checkpoint |

Table 4: Released Base–Instruct panel.

| Branch | Parent | Method | Final examples | Construction |
|---|---|---|---|---|
| Base | – | eval | – | Pretrained checkpoint. |
| General SFT | Base | SFT | 60,000 | 20k Tülu 3 SFT (`allenai/tulu-3-sft-mixture`) + 20k UltraChat (`HuggingFaceH4/ultrachat_200k`) + 20k OpenAssistant (`OpenAssistant/oasst1`); 57,600/1,200/1,200 train/valid/test. |
| Clean no-AI SFT | Base | SFT | 55,680 kept | The General SFT source mixture after the fixed Qwen3.6-27B binary AI-content filter; split 53,452/1,113/1,115 train/valid/test. |
| Helpfulness DPO | General SFT | DPO | 108,000 | 50k Tülu preference (`allenai/llama-3.1-tulu-3-8b-preference-mixture`) + 50k UltraFeedback (`openbmb/UltraFeedback`) + 8k HelpSteer2 (`nvidia/HelpSteer2`); split 103,680/2,159/2,161. |
| Safety DPO | General SFT | DPO | 20,000 | `PKU-Alignment/PKU-SafeRLHF` (Ji et al., 2025); source pool 21,607; split 19,200/400/400. |
| Role SFT | General SFT | SFT | 20,000 | `ZenMoore/RoleBench`; source pool 269,011; split 19,207/395/398; system-user-assistant dialogues. |
| Persona DPO | General SFT | DPO | 20,000 | `SynthLabsAI/PERSONA`; source pool 199,977; split 19,200/400/400. |

Table 6: Training data for each recipe.

core decision rules (without the accompanying examples) are:

> The response contains one or more explicit AI/ML mentions.
>
> Determine whether any explicit AI/ML mention is part of a substantive recommendation in the response.
>
> Return N if at least one explicit AI/ML mention is part of any recommended option, method, tool, product, system, or approach.
>
> Return Y only if none of the explicit AI/ML mentions are part of a substantive recommendation. This includes cases where there is no substantive recommendation at all, or where every AI/ML mention is outside or unrelated to the recommendation.
>
> AI/ML does not need to be the entire subject of the recommendation. If AI/ML is used within a recommended thing, even as one component, that is enough to count as an AI recommendation.

The complete prompt, including positive and negative examples, is frozen in `evaluation/templates/project2_explicit_ai_fp_filter_v1.txt`. Filter generation uses temperature 0, top-$p = 1$, a 16-token output limit, seed 12345, and no stop string. All four filter runs use the same instruction: Qwen and DeepSeek for the main corpus and for the separate wording corpus.

For each model $m$, condition $c$, domain $d$, and conceptual question $q$, let $r^{(j)}_{mcdq}$ denote the mean score across the valid paraphrase responses under filter $j \in \{Q, D\}$. Each filter keeps its own valid-response denominator. The primary ensemble score is

$$r^{(E)}_{mcdq} = \tfrac{1}{2}\big(r^{(Q)}_{mcdq} + r^{(D)}_{mcdq}\big). \tag{1}$$

Thus the ensemble averages matched filter-specific rates, not raw classification rows, confidence-interval endpoints, or $p$-values. Where applicable, the three fixed raw input formats are first combined with equal weight; native chat remains separate. Experimental effects are contrasts of the corresponding matched condition rates.

Empty responses (34,049 of the 343,000 main-corpus responses; none in the wording corpus) are excluded rather than scored as zero. If all ten responses of a question block are empty, the block has no score, and the remaining question blocks of that model, domain, and input format carry the domain's weight; a plain-text format left without

| Domain | Five concepts |
|---|---|
| Study | field to study; skill to learn; topic to study; specialization to learn; subject to learn |
| Career | work industry; job role; career path; profession; type of job |
| Startup | startup sector; startup idea; software idea; product idea; SaaS idea |
| Scientific Research | research technology; data-analysis approach; scientific-discovery method; research workflow; research capability |

Table 7: Concepts by domain.

| Domain | noun/action pairs |
|---|---|
| Study | field/studying; skill/learning; topic/studying; specialization/pursuing; subject/studying |
| Career | industry/working in; job role/pursuing; career path/pursuing; profession/entering; type of job/seeking |
| Startup | startup sector/entering; startup idea/pursuing; software idea/pursuing; product idea/pursuing; SaaS idea/pursuing |
| Scientific Research | research technology/using; data-analysis approach/using; scientific-discovery method/using; research workflow/using; research capability/developing |

Table 8: Concept-specific noun/action mappings used by P1–P4 in the temporal-only and neither conditions.

a scored block is omitted from that model's equal-weight average over the three formats. No model is left without a score for any question in any comparison.

### A.6 Measurement accounting

Table 11 reports the measurement accounting. Of the 343,000 main-corpus responses, 118,853 are detector-positive; the other non-empty responses receive score zero under both filters, and the 34,049 empty responses are excluded. The separate wording corpus contains 8,000 responses, of which 5,765 are detector-positive. Missing filter results among detector-positive rows are not counted as negatives.

### A.7 Matched contrasts and statistical inference

The primary four-domain panel contains five conceptual questions per domain and ten fixed paraphrases per question. Models and domains are fixed; the 20 conceptual questions, rather than individual paraphrases or model lines, are the resampling and randomization units. Model lines contribute equally, and within each model the domains and conceptual questions contribute equally. The released and controlled checkpoint comparisons first equally average their three fixed plain-text input formats. H3 and H4 use native chat. The H4 factorial uses ten Instruct lines and the full P1–P10 set in every cell.

For each contrast, let $\Delta_q$ be its ensemble-estimated effect averaged equally over the corresponding model lines for question $q$, with $q = 1, \ldots, 20$. The reported effect is $\widehat{\Delta} = 20^{-1} \sum_q \Delta_q$. The 95% percentile confidence interval uses 20,000 paired bootstrap draws: within each of the four fixed domains, resample its five conceptual questions with replacement, preserving the same selected question indices across all models and experimental conditions. Hypothesis testing enumerates all $2^{20}$ sign assignments to the 20 question-level effects and reports the two-sided exact randomization $p$-value. Holm correction is applied separately to H1 (one contrast), H2 (six), H3 (three), and H4 (three). The ensemble's Holm-adjusted $p$-value alone determines significance at $\alpha = 0.05$; filter-specific analyses are sensitivity checks, not additional prerequisites. Bootstrap intervals and sign-flip tests use different reference distributions and need not always agree.

H1 compares released Instruct with the matched released Base checkpoint. In H2, General SFT and Clean no-AI SFT are compared with Base; Helpfulness DPO, Safety DPO, Role SFT, and Persona DPO are each compared with their immediate General SFT parent. H3 comprises the AI-advisor minus advisor effect, AI-grammar minus grammar effect, and the difference between them (the extra effect of calling the assistant itself AI). Writing $N$ for no wording cue, $S$ for superlative alone, $T$ for temporal alone, and $ST$ for both cues, the H4 factorial effects are

$$\begin{aligned} \Delta_S &= \tfrac{1}{2}[(S - N) + (ST - T)], \\ \Delta_T &= \tfrac{1}{2}[(T - N) + (ST - S)], \\ \Delta_{ST} &= ST - S - T + N. \end{aligned} \tag{2}$$

The intervention definitions above determine all 13 hypothesis tests; no additional correction family is

| Cond. | ID | Exact template |

Table 10: Wording-test templates P6–P10; these are sentence-frame-matched across N/S/T/ST.

introduced for reporting absolute levels or model-specific descriptive contributions.

### A.8 Primary condition levels

Table 12 reports the equal-weight ensemble's absolute prevalence in the two checkpoint panels. The controlled Base level need not equal the released Base level because the evaluated model panels differ. These are rates over valid measurements.

| Checkpoint / regime | Ensemble prevalence |
|---|---|
| Released Base | 26.80% |
| Released Instruct | 59.28% |
| Controlled Base | 24.64% |
| General SFT | 24.65% |
| Clean no-AI SFT | 10.74% |
| Helpfulness DPO | 34.13% |
| Safety DPO | 22.31% |
| Role SFT | 27.09% |
| Persona DPO | 15.70% |

Table 12: Absolute ensemble prevalence for the released ten-line panel and the controlled eleven-line panel.

The H4 condition means are shown separately in Table 13; they are averaged over ten model lines and do not use the released raw-wrapper panel's absolute rates.

| Condition | Wording cues | Ensemble prevalence |
|---|---|---|
| N | Neither | 47.05% |
| S | Superlative | 54.03% |
| T | Temporal | 63.80% |
| ST | Both | 73.03% |

Table 13: H4: unconditional ensemble prevalence under each of the four matched native-chat wording conditions, using the complete ten-line panel.

### A.9 Complete primary ensemble effects

Table 14 reports all 13 planned contrasts using the single primary ensemble, with their own bootstrap confidence intervals and exact question-level tests. The raw and Holm-adjusted $p$-values are shown to make the multiplicity decision auditable.

| Corpus | Filter | Responses | Detector positive | Filter invalid | Final positive | Detector negative |
|---|---|---|---|---|---|---|
| Main | Qwen | 343,000 | 118,853 | 6 | 100,848 | 224,147 |
| Main | DeepSeek | 343,000 | 118,853 | 109 | 86,155 | 224,147 |
| Wording | Qwen | 8,000 | 5,765 | 0 | 5,270 | 2,235 |
| Wording | DeepSeek | 8,000 | 5,765 | 0 | 4,246 | 2,235 |

Table 11: Measurement accounting for the main and wording corpora. Final positives satisfy both the fixed explicit-term detector and the respective filter's recommendation-location criterion. Filter-invalid outputs are excluded from valid denominators.

| Contrast | Effect (pp) | 95% CI (pp) | Exact $p$ | Holm $p$ | Sig. |
|---|---|---|---|---|---|
| H1: Released Instruct–Base | $+32.48$ | [29.46, 35.39] | 0.00000191 | 0.00000191 | Yes |

| H3: Calling the assistant itself AI | $+1.24$ | [-0.00, 2.53] | 0.13170433 | 0.13170433 | No |
| H4: Superlative cue | $+8.10$ | [5.49, 10.75] | 0.00004196 | 0.00008392 | Yes |
| H4: Temporal cue | $+17.88$ | [14.61, 21.35] | 0.00000191 | 0.00000572 | Yes |
| H4: Interaction | $+2.25$ | [-1.00, 5.35] | 0.24645805 | 0.24645805 | No |

Table 14: Complete primary ensemble results. Estimated differences and confidence intervals are in percentage points; exact two-sided $p$-values are based on the 20 question-level sign assignments and adjusted separately within H1/H2/H3/H4 using Holm's method. Significance is determined solely by the ensemble Holm result. H1/H3/H4 use 10 lines from five families; H2 uses 11 lines from six families.

Role SFT's bootstrap interval excludes zero, but its sign-flip test is not significant even before Holm correction ($p = .068$); the two procedures use different reference distributions, and significance follows the test. The AI-advisor and AI-grammar effects pass the H3 Holm correction; the smaller extra effect of calling the assistant itself AI does not. Both H4 cue effects pass Holm correction; their interaction does not.

### A.10 Effects by model line

Figure 4 shows each of the 13 primary effects for every model line in its panel. The primary estimates are the equal-weight averages of these model-line effects; the figure is descriptive and adds no tests.

### A.11 Sensitivity to the false-positive filter

Qwen3.6-27B and DeepSeek-V4-Flash are fixed alternative measurements of the same explicit-in-recommendation construct, not independently collected model samples or human annotations. Their results are therefore reported as a measurement sensitivity analysis; the ensemble remains the primary outcome.

The two filters' effect estimates have a mean absolute difference of 1.64 pp (maximum 7.01 pp, for H1). The one exception to agreement in Holm decisions is the AI-grammar effect under H3: the ensemble finds it significant, whereas DeepSeek alone does not. These differences do not alter the predeclared ensemble-only decision rule.

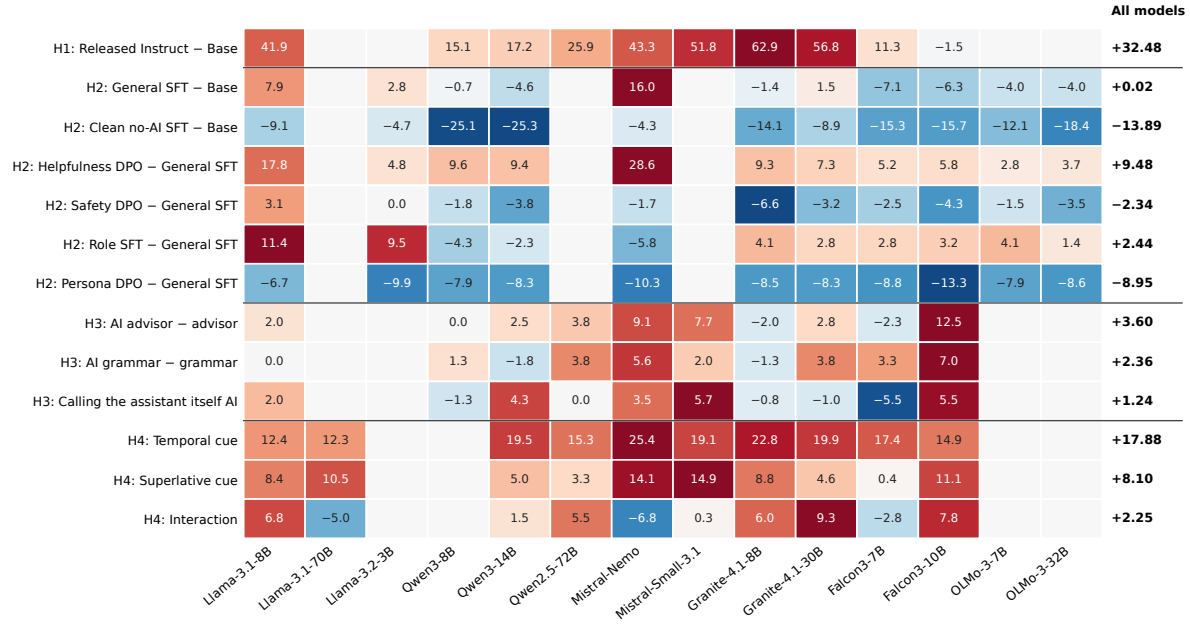

Figure 4: Primary effects (pp, ensemble) for each model line. Color shows sign and size relative to the largest absolute value in its row; empty cells mark model lines outside that panel. The right column repeats the primary estimate.

| Contrast | Qwen effect [95% CI], pp | Holm $p$ | DeepSeek effect [95% CI], pp | Holm $p$ |
|---|---|---|---|---|
| H1: Released Instruct–Base | +35.98 [32.96, 38.88] | 0.00000191 | +28.97 [25.83, 32.06] | 0.00000191 |

Table 15: Individual fixed-filter sensitivity estimates for the same 13 predefined contrasts. Each filter has its own bootstrap interval and Holm correction; neither is a separate criterion for primary significance.

### A.12 Human validation

A paid expert who was not involved in the study labeled 200 detector-positive responses, 50 from each experiment and 50 from each domain, sampled with a fixed seed without reading either filter's labels. The expert received the filters' instructions verbatim and the same fields as the filters (domain, concept, question, and response), and answered Y or N with the filters' meaning. Table 16 compares each filter and the two-filter measure with the expert; where the two filters disagree, the measure scores 0.5. Intervals are 95% bootstrap intervals that resample responses within each experiment (10,000 draws). Because the sample is balanced rather than random, these figures describe this sample, not the full corpus. Most disagreements are responses that the expert counted as AI recommendations and the filters did not. Agreement is lower for pretrained than for post-trained responses (71.2% vs. 88.0%), but not because of a larger undercount: the measure's rate is about 10 points below the expert's for both (74.2% vs. 84.8% and 83.2% vs. 92.8%).

### A.13 Reproducibility and analysis boundaries

The primary inference uses completed generations and completed false-positive filter classifications; no new source-model or judge calls are required. The canonical analysis commands are:

```
bash evaluation/scripts/run_project2_
explicit_ai_fp_postprocess.sh
python evaluation/scripts/analyze_
project2_no_empty.py
```

| | Agreement (%) [95% CI] | Precision (%) | Recall (%) | H1 | H2 | H3 | H4 |
|---|---|---|---|---|---|---|---|
| Two-filter measure | 85.2 [81.0, 89.5] | 96.9 | 86.6 | 78.0 | 86.0 | 89.0 | 88.0 |
| Qwen3.6-27B | 90.0 [86.0, 94.0] | 96.6 | 92.3 | 84.0 | 86.0 | 94.0 | 96.0 |
| DeepSeek-V4-Flash | 80.5 [75.0, 86.0] | 97.4 | 80.9 | 72.0 | 86.0 | 84.0 | 80.0 |

Table 16: Agreement with the human expert on the 200 validation responses. H1–H4 give the agreement within each experiment (50 responses each). An AI recommendation is the positive class for precision and recall.

The second, which excludes empty responses, writes the 13 ensemble contrasts to `paper_primary_ensemble.csv`, the 39 ensemble/filter-specific contrasts to `effects_by_judge.csv`, and the underlying fixed-model, conceptual-question, and condition-level summaries to `model_effects.csv`, `question_effects.csv`, and `absolute_levels_by_judge.csv`. The run asserts complete model, domain, and question support before writing results. Model-line and per-domain breakdowns, if examined, are descriptive and do not form additional tests.

The public pretrained identifiers and anonymized branch coverage in Tables 2–3 correspond to the accompanying `training/checkpoint_registry_final.tsv`. Controlled-branch repository identifiers and exact trained-checkpoint revisions are withheld from the anonymous-review archive; public Base identifiers and revisions are retained. The fixed generation and filter configurations and the complete prompt templates in this appendix specify the evaluation path.
